7 This paper describes a simple heuristic approach to solving large-scale con-  
8 straint satisfaction and scheduling problems. In this approach one starts  
9 with an inconsistent assignment for a set of variables and searches through  
10 the space of possible repairs. The search can be guided by a value-ordering  
11 heuristic, the *min-conflicts heuristic*, that attempts to minimize the num-  
12 ber of constraint violations after each step. The heuristic can be used with  
13 a variety of different search strategies. We demonstrate empirically that on  
14 the  $n$ -queens problem, a technique based on this approach performs orders of  
15 magnitude better than traditional backtracking techniques. We also describe  
16 a scheduling application where the approach has been used successfully. A  
17 theoretical analysis is presented both to explain why this method works well  
18 on certain types of problems and to predict when it is likely to be most  
19 effective.

## 1 Introduction

For continuous integration (CI) and build systems a lot of it is configured with code as configuration. The main kind of configuration format used for this is yaml followed by xml and special edge cases. As CI is increasingly becoming more popular and practical ().....For software development teams there are roles for just looking after and managing CI and the deployment infrastructure. Understanding how code as configuration is used for CI is an emerging area of research because of this.

As Travis CI is the most popular research has already be done on patterns found in the structure Gallaba and McIntosh (2018). We will follow a similar methodology in order to get our data to analyse.

Although we won't be looking at puppet () research has also be done on the "code smell" which can be an indication on the quality of the code by analyzing its structure Sharma, Fragkoulis and Spinellis (2016).

Initially this paper started off looking at how to visualize Continuous Integration (CI) and Continuous delivery (CD) systems. However due to their being a lack of research in the area () on specifically on how CI is used and practical implementation. A lot of research has been done supporting the use of CI/CD and it's implementation and benefits in cases for particular languages.

## 2 Previous Works

By almost any measure, the Hubble Space Telescope scheduling problem Between ten thousand and thirty thousand astronomical observations per year must be scheduled, subject to a great variety of constraints including power restrictions, observation priorities, time-dependent orbital characteristics, movement of astronomical bodies, stray light sources, etc. Because the telescope is an extremely valuable resource with a limited lifetime, efficient scheduling is a critical concern. An initial scheduling system, developed using traditional programming methods, highlighted the difficulty of the prob-

51 lem; it was estimated that it would take over three weeks for the system to  
52 schedule one week of observations. As described in section 4, this problem  
53 was remedied by the development of a successful constraint-based system to  
54 augment the initial system. At the heart of the constraint-based system is  
55 a neural network developed by Adorf and Johnston, the Guarded Discrete  
56 Stochastic (GDS) network,

57 From a computational point of view the network is interesting because  
58 Adorf and Johnston found that it performs well on a variety of tasks, in  
59 addition to the space telescope scheduling problem. For example, the network  
60 performs significantly better on the  $n$ -queens problem than methods that  
61 were previously developed. The  $n$ -queens problem requires placing  $n$  queens  
62 on an  $n \times n$  chessboard so that no two queens share a row, column or diagonal.  
63 The network has been used to solve problems of up to 1024 queens, whereas  
64 most heuristic backtracking methods encounter difficulties with problems  
65 one-tenth

66 In a standard Hopfield network, all connections between neurons are sym-  
67 metric. In the GDS network, the main network is coupled asymmetrically to  
68 an auxiliary network of *guard neurons* which restricts the configurations that  
69 the network can assume. This modification enables the network to rapidly  
70 find a solution for many problems, even when the network is simulated on  
71 a serial machine. Unfortunately, convergence to a stable configuration is no  
72 longer guaranteed. Thus the network can fall into a local minimum involving  
73 a group of unstable states among which it will oscillate. In practice, however,  
74 if the network fails to converge after some number of neuron state transitions,  
75 it can simply be stopped and started over.

76 To illustrate the network architecture and updating scheme, let us con-  
77 sider how the network is used to solve binary constraint satisfaction problems.  
78 A problem consists of  $n$  variables,  $X_1 \dots X_n$ , with domains  $D_1 \dots D_n$ , and a  
79 set of binary constraints. Each constraint  $C_\alpha(X_j, X_k)$  is a subset of  $D_j \times D_k$   
80 specifying incompatible values for a pair of variables. The goal is to find  
81 an assignment for each of the variables which satisfies the constraints. (In

82 this paper we only consider the task of finding a single solution, rather than  
 83 that of finding all solutions.) To solve a CSP using the network, each vari-  
 84 able is represented by a separate set of neurons, one neuron for each of the  
 85 variable’s possible values. Each neuron is either “on” or “off”, and in a solu-  
 86 tion state, every variable will have exactly one of its corresponding neurons  
 87 “on”, representing the value of that variable. Constraints are represented by  
 88 inhibitory (i.e., negatively weighted) connections between the neurons. To  
 89 insure that every variable is assigned a value, there is a guard neuron for  
 90 each set of neurons representing a variable; if no neuron in the set is on, the  
 91 guard neuron will provide an excitatory input that is large enough to turn  
 92 one on. (Because of the way the connection weights are set up, it is unlikely  
 93 that the guard neuron will turn on more than one neuron.) The network is  
 94 updated on each cycle by randomly picking a set of neurons that represents  
 95 a variable, and flipping the state of the neuron in that set whose input is  
 96 *most inconsistent* with its current output (if any). When all neurons’ states  
 97 are consistent with their input, a solution is achieved.

98 To solve the  $n$ -queens problem, for example, each of the  $n \times n$  board posi-  
 99 tions is represented by a neuron whose output is either one or zero depending  
 100 on whether a queen is currently placed in that position or not. (Note that  
 101 this is a local representation rather than a distributed representation of the  
 102 board.) If two board positions are inconsistent, then an inhibiting connection  
 103 exists between the corresponding two neurons. For example, all the neurons  
 104 in a column will inhibit each other, representing the constraint that two  
 105 queens cannot be in the same column. For each row, there is a guard neuron  
 106 connected to each of the neurons in that row which gives the neurons in the  
 107 row a large excitatory input, enough so that at least one neuron in the row  
 108 will turn on. The guard neurons thus enforce the constraint that one queen  
 109 in each row must be on. As described above, the network is updated on each  
 110 cycle by randomly picking a row and flipping the state of the neuron in that  
 111 row whose input is most inconsistent with its current output. A solution is  
 112 realized when the output of every neuron is consistent with its input.

## 113 3 Why does the GDS Network Perform So 114 Well?

115 Our analysis of the GDS network was motivated by the following question:  
116 “Why does the network perform so much better than traditional backtracking  
117 methods on certain tasks”? In particular, we were intrigued by the results on  
118 the  $n$ -queens problem, since this problem has received considerable attention  
119 from previous researchers. For  $n$ -queens, Adorf and Johnston found empir-  
120 ically that the network requires a linear number of transitions to converge.  
121 Since each transition requires linear time, the expected (empirical) time for  
122 the network to find a solution is  $O(n^2)$ . To check this behavior, Johnston  
123 and Adorf ran experiments with  $n$  as high as 1024, at which point memory  
124 limitations became a problem.<sup>1</sup>

### 125 3.1 Nonsystematic Search Hypothesis

126 Initially, we hypothesized that the network’s advantage came from the non-  
127 systematic nature of its search, as compared to the systematic organization  
128 inherent in depth-first backtracking. There are two potential problems as-  
129 sociated with systematic depth-first search. First, the search space may be  
130 organized in such a way that poorer choices are explored first at each branch  
131 point. For instance, in the  $n$ -queens problem, depth-first search tends to find  
132 a solution more quickly when the first queen is placed in the center of the  
133 first row rather than in the corner; apparently this occurs because there are  
134 more solutions with the Queen in the center. Nevertheless, most naive algorithms tend to start  
135 in the corner simply because humans find it more natural to program that  
136 way. However, this fact by itself does not explain why nonsystematic search  
137 would work so well for  $n$ -queens. A backtracking program that randomly

---

<sup>1</sup>The network, which is programmed in Lisp, requires approximately 11 minutes to solve the 1024 queens problem on a TI Explorer II. For larger problems, memory becomes a limiting factor because the network requires approximately  $O(n^2)$  space. (Although the number of connections is actually  $O(n^3)$ , some connections are computed dynamically rather than stored).

Figure 1: Solutions Clustered vs. Solutions Evenly Distributed

orders rows (and columns within rows) performs much better than the naive method, but still performs poorly relative to the GDS network.

The second potential problem with depth-first search is more significant and more subtle. As illustrated by figure 1, a depth-first search can be a disadvantage when solutions are not evenly distributed throughout the search space. In the tree at the left of the figure, the solutions are clustered together. In the tree on the right, the solutions are more evenly distributed. Thus, the average distance between solutions is greater in the left tree. In a depth-first search, the average time to find the first solution increases with the average distance between solutions. Consequently depth-first search performs relatively poorly in a tree where solutions are clustered. In comparison, a search strategy which examines the leaves of the tree in random order is unaffected by solution clustering.

We investigated whether this phenomenon explained the relatively poor performance of depth-first search on  $n$ -queens by experimenting with a randomized algorithm. The algorithm begins by selecting a path from the root to a leaf. To select a path, the algorithm starts at the root node and chooses one of its children with equal probability. This process continues recursively until a leaf is encountered. If the leaf is a solution the algorithm terminates, if not, it starts over again at the root and selects a path. The same path may be examined more than once, since no memory is maintained between successive

159 trials.

160 The Las Vegas algorithm does, in fact, perform better than simple depth-  
161 first search on  $n$ -queens. However, the performance of the Las Vegas algorithm  
162 is still not nearly as good as that of the GDS network, and so we concluded  
163 that the systematicity hypothesis alone cannot explain the network's behav-  
164 ior.

### 165 3.2 Informedness Hypothesis

166 Our second hypothesis was that the network's search process uses informa-  
167 tion about the current assignment that is not available to a constructive  
168 backtracking program. Its use of an iterative improvement strategy guides  
169 the search in a way that is not possible with a standard backtracking algo-  
170 rithm. We now believe this hypothesis is correct, in that it explains why the  
171 network works so well. In particular, the key to the network's performance  
172 appears to be that state transitions are made so as to reduce the number of  
173 outstanding inconsistencies in the network; specifically, each state transition  
174 involves flipping the neuron whose output is most inconsistent with its cur-  
175 rent input. From a constraint satisfaction perspective, it is as if the network  
176 reassigns a value for a variable by choosing the value that violates the fewest  
177 constraints. This idea is captured by the following heuristic:

#### 178 **Min-Conflicts heuristic:**

179 *Given:* A set of variables, a set of binary constraints, and an assign-  
180 ment specifying a value for each variable. Two variables *conflict* if  
181 their values violate a constraint.

182 *Procedure:* Select a variable that is in conflict, and assign it a value  
183 that minimizes the number of conflicts. (Break ties randomly.)

184 We have found that the network's behavior can be approximated by a  
185 symbolic system that uses the min-conflicts heuristic for hill climbing. The  
186 hill-climbing system starts with an initial assignment generated in a prepro-  
187 cessing phase. At each choice point, the heuristic chooses a variable that is

188 currently in conflict and reassigns its value, until a solution is found. The  
189 system thus searches the space of possible assignments, favoring assignments  
190 with fewer total conflicts. Of course, the hill-climbing system can become  
191 “stuck” in a local maximum, in the same way that the network may become  
192 “stuck” in a local minimum. In the next section we present empirical evi-  
193 dence to support our claim that the min-conflicts approach can account for  
194 the network’s effectiveness.

195     There are two aspects of the min-conflicts hill-climbing method that dis-  
196 tinguish it from standard CSP algorithms. First, instead of incrementally  
197 constructing a consistent partial assignment, the min-conflicts method *re-*  
198 *pairs* a complete but inconsistent assignment by reducing inconsistencies.  
199 Thus, it uses information about the current assignment to guide its search  
200 that is not available to a standard backtracking algorithm. Second, the use  
201 of a hill-climbing strategy rather than a backtracking strategy produces a  
202 different style of search.

### 203 3.2.1 Repair-Based Search Strategies

204 (This is a example of a third level section.) Extracting the method from the  
205 network enables us to tease apart and experiment with its different compo-  
206 nents. In particular, the idea of repairing an inconsistent assignment can be  
207 used with a variety of different search strategies in addition to hill climbing.  
208 For example, we can backtrack through the space of possible repairs, rather  
209 than using a hill-climbing strategy, as follows. Given an initial assignment  
210 generated in a preprocessing phase, we can employ the min-conflicts heuristic  
211 to order the choice of variables and values to consider, as described in figure  
212 2. Initially, the variables are all on a list of VARS-LEFT, and as they are  
213 repaired, they are pushed onto a list of VARS-DONE. The algorithm attempts  
214 to find a sequence of repairs, such that no variable is repaired more than  
215 once. If there is no way to repair a variable in VARS-LEFT without violat-  
216 ing a previously repaired variable (a variable in VARS-DONE), the algorithm  
217 backtracks.

```

Procedure INFORMED-BACKTRACK (VARS-LEFT VARS-DONE)
  If all variables are consistent, then solution found, STOP.
  Let VAR = a variable in VARS-LEFT that is in conflict.
  Remove VAR from VARS-LEFT.
  Push VAR onto VARS-DONE.
  Let VALUES = list of possible values for VAR in ascending order according
                  to number of conflicts with variables in VARS-LEFT.
  For each VALUE in VALUES, until solution found:
    If VALUE does not conflict with any variable that is in VARS-DONE,
    then Assign VALUE to VAR.
      Call INFORMED-BACKTRACK(VARS-LEFT VARS-DONE)
    end if
  end for
end procedure

Begin program
  Let VARS-LEFT = list of all variables, each assigned an initial value.
  Let VARS-DONE = nil
  Call INFORMED-BACKTRACK(VARS-LEFT VARS-DONE)
End program

```

Figure 2: Informed Backtracking Using the Min-Conflicts Heuristic

218 Notice that this algorithm is simply a standard backtracking algorithm  
219 augmented with the min-conflicts heuristic to order its choice of which vari-  
220 able and value to attend to. This illustrates an important point. The back-  
221 tracking repair algorithm incrementally extends a consistent partial assign-  
222 ment (i.e., VARS-DONE), as does a constructive backtracking program, but  
223 in addition, uses information from the initial assignment (i.e., VARS-LEFT)  
224 to bias its search. Thus, it is a type of *informed backtracking*. We still char-  
225 acterize it as repair-based method since its search is guided by a complete,  
226 inconsistent assignment.
